segmentation of one–dim. signals and contours:

- segmentation of one–dim. signals
  - problem formulation: squared error criterion
  - optimization method: dynamic programming
  - extensions: error criterion: absolute value error
    probabilistic model (maximum likelihood estimation)
  - model: general case
  - model: straight line

- segmentation of image contours ( = two–dim. signals)
  - problem formulation
  - error criterion: vertical vs. orthogonal least squares
  - model: straight lines ( = polygon approximation)
  - model: circular arcs
  - use of prior knowledge
contour finding and image matching:

- contour finding in images
  - problem formulation – one-dim. contour: \( x \rightarrow y(x) \)
  - two-dim. contour: \( n \rightarrow [x_n, y_n] \)
  - use of prior knowledge

- image registration and matching
  - HMM (Hidden Markov Model): matching for one-dim. signals
  - Pseudo 2-D HMM
  - Moore’s algorithm
  - Sakoe’s algorithm

REFERENCES: 2-D Methods

ONE-DIM. SIGNALS
constant function:

We are given a sequence of one–dim. measurements:

\[ x_n \in \mathbb{R}, \quad n = 1, \ldots, N \]

We want to segment this sequence into \( k = 1, \ldots, K \) segments. Each segment \( k \) is represented by a constant but unknown value \( a_k \).

The quantitative criterion is based on using the squared error:

\[ \sum_{n=n_{k-1}+1}^{n_k} [x_n - a_k]^2 \]

The global criterion then is to optimize over the unknown segment boundaries

\[ n_1, \ldots, n_k, \ldots, n_K : = n_K^1 \]

with the definitions:

\[ 0 \equiv n_0 < n_1 < \ldots < n_{k-1} < n_k < \ldots < n_K \equiv N \]
segmentation of one–dim. signals
The criterion is to select the boundaries such that the sum over all local squared errors is a minimum:

\[
\min_{n_1^K} \sum_{k=1}^{K} \min_{\alpha_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} [x_n - \alpha_k]^2 \right\}
\]

where also the constant value \( \alpha_k \) for each segment \( k \) is unknown.

Number of possible segmentations:

\[
\binom{N-1}{K-1} \approx \frac{(N-1)^{K-1}}{(K-1)!} \quad \text{[for } N \gg K]\]

We will design an algorithm (based on dynamic programming) with time complexity:

\[ K \cdot N^2 \]
constant function: local optimization over \( a_k \)

optimal value \( a_k \) for each segment \( k \):

for each segment with boundaries \( n = n_{k-1} + 1 \) and \( n = n_k \), we have:

\[
\min_{a_k} \sum_{n=n_{k-1}+1}^{n_k} [x_n - a_k]^2
\]

To carry out the minimization over \( a_k \), we observe:

\[
\sum_{m=1}^{M} [y_m - A]^2 = \sum_{m} y_m^2 - 2A \sum_{m} y_m + M \cdot A^2 = M \cdot \left[ A - \frac{1}{M} \sum_{m} y_m \right]^2 + \sum_{m} y_m^2 - \frac{1}{M} \left( \sum_{m} y_m \right)^2
\]

and we obtain:

\[
\arg \min_{A} \sum_{m=1}^{M} [y_m - A]^2 = \frac{1}{M} \sum_{m} y_m =: \bar{y}
\]

\[
\min_{A} \sum_{m=1}^{M} [y_m - A]^2 = \sum_{m} y_m^2 - \frac{1}{M} \left( \sum_{m} y_m \right)^2 = \sum_{m} y_m^2 - M \bar{y}^2
\]
We introduce the auxiliary function $G(k, n)$:

$$G(k, n) := \min_{n_1^k : n_k = n} \left\{ \sum_{\kappa=1}^{k} \min_{a_{\kappa}} \sum_{i=n_{\kappa}-1+1}^{n_{\kappa}} [x_i - a_{\kappa}]^2 \right\}$$

i.e. the error of the best decomposition of the partial sequence $x_1^n$ into $k$ segments.

We decompose this quantity for $k$ segments by going back to $(k - 1)$ segments:

$$G(k, n) =$$

$$= \min_{n_1^{k-1} : n_k = n} \left\{ \sum_{\kappa=1}^{k-1} \min_{a_{\kappa}} \sum_{i=n_{\kappa}-1+1}^{n_{\kappa}} [x_i - a_{\kappa}]^2 + \min_{a_k} \sum_{i=n_{k-1}+1}^{n_k} [x_i - a_k]^2 \right\}$$

$$= \min_m \left\{ \sum_{n_1^{k-1} : n_k = m} \left( \sum_{\kappa=1}^{k-1} \min_{a_{\kappa}} \sum_{i=n_{\kappa}-1+1}^{n_{\kappa}} [x_i - a_{\kappa}]^2 \right) + \min_{a_k} \sum_{i=m+1}^{n} [x_i - a_k]^2 \right\}$$

$$= \min_m \left\{ G(k - 1, m) + \min_{a_k} \sum_{i=m+1}^{n} [x_i - a_k]^2 \right\}$$
The approach we have applied is the following:

The original problem has been decomposed into smaller problems. We solve these smaller problems and compose the global solution from the solution to the smaller problems.

other algorithms based on dynamic programming:
– CYK parsing for context free grammars (CYK = Cocke–Younger–Kasami)
– Viterbi algorithm for finding the best path in Hidden Markov models
– algorithm for knapsack problem
– ...
To reconstruct the optimal segmentation, we introduce so-called backpointers $B(k, n)$ which keep track of the optimal segmentation when going from $(k - 1)$ to $k$ segments. Thus we obtain the recursion:

$$G(k, n) = \min_{m} \left\{ G(k - 1, m) + \min_{a_k} \sum_{i=m+1}^{n} [x_i - a_k]^2 \right\}$$

$$B(k, n) = \arg \min_{m} \left\{ G(k - 1, m) + \min_{a_k} \sum_{i=m+1}^{n} [x_i - a_k]^2 \right\}$$

Note:

- This recursion should be implemented in the so-called ITERATIVE variant, i.e. by using an array or table for $G(k, n)$ (and $B(k, n)$).

- Alternative implementation:
  MEMOIZATION := recursive implementation + lookup table

resulting complexity (without the sum, i.e. using running sums): $K \cdot N^2$

modification: maximum segment length $\Delta N$: $K \cdot N \cdot \Delta N$
segmentation of one–dim. signals: dynamic programming

\[ k \]
\[ k-1 \]
\[ m \]
\[ n \]

</tbody>
</table>

note: use running sums for $\sum_i [x_i - a_k]^2$
To efficiently calculate \( \sum_{i=m+1}^{n} [x_i - a]^2 \) for varying \( m, n, a \), we compute only once (for all \( n = 1, \ldots, N \)):

\[
S_n = \sum_{i=1}^{n} x_i \quad Q_n = \sum_{i=1}^{n} x_i^2
\]

then, we observe:

\[
\sum_{i=m+1}^{n} [x_i - a]^2 = \sum_{i=m+1}^{n} [x_i^2 - 2ax_i + a^2] = \sum_{i=m+1}^{n} x_i^2 - 2a \sum_{i=m+1}^{n} x_i + a^2 = Q_n - Q_m - 2a(S_n - S_m) + a^2
\]
The squared error is replaced by the absolute value error:

$$\min_{n \in K} \sum_{k=1}^{K} \min_{a_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} |x_n - a_k| \right\}$$

- **advantage**: more robust with respect to outliers
- **disadvantage**: the optimum value $a_k$ is the median, which is expected to require more computation
probability distribution:
we assume a functional dependence for each model of segment $k$:

$$p_k(x | \lambda_k)$$

with a suitable parameter set $\lambda_k$.

The criterion is to find the segment boundaries $n_1^K$ such that the sum over the negative logarithms of the probability model is a minimum:

$$\min_{n_1^K} \sum_{k=1}^K \min_{\lambda_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} \left[ -\log p_k(x_n | \lambda_k) \right] \right\}$$

Here, the negative logarithm of the probability model $[-\log p_k(x_n | \lambda_k)]$ is interpreted as local error $[x_n - \hat{x}_n(k; \lambda_k)]^2$. 
This is equivalent to maximizing the product of the probabilities over the unknown segment boundaries $n^K_1$ and the unknown parameter sets $\lambda^K_1$:

$$\max_{n^K_1} \prod_{k=1}^{K} \max_{\lambda^K_k} \left\{ \prod_{n=n_{k-1}+1}^{n_k} p_k(x|\lambda_k) \right\}$$

It is easy to see that we obtain the same type of dynamic programming recursion.

note: there is NO constraint on the continuity of the segments at the boundaries.
probability distribution:

\[ p_k(x | \lambda_k) = \mathcal{N}(x | \mu_k, \sigma_k^2) \]

\[ = \frac{1}{\sqrt{2\pi\sigma_k^2}} \cdot \exp \left[ -\frac{1}{2\sigma_k^2} (x - \mu_k)^2 \right] \]

\[-\log \mathcal{N}(x | \mu_k, \sigma_k^2) = \frac{1}{2} \log (2\pi\sigma_k^2) + \frac{1}{2\sigma_k^2} (x - \mu_k)^2 \]

case I: unknown means \( \mu_k \) and known variances \( \sigma_k^2 \):

\[ \min_{n_1} \sum_{k=1}^{K} \min_{\mu_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} \left[ -\log \mathcal{N}(x_n | \mu_k, \sigma_k^2) \right] \right\} \]

case II: unknown means \( \mu_k \) and unknown variances \( \sigma_k^2 \):

\[ \min_{n_1} \sum_{k=1}^{K} \min_{\mu_k, \sigma_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} \left[ -\log \mathcal{N}(x_n | \mu_k, \sigma_k^2) \right] \right\} \]

case III: unknown means \( \mu_k \) and (known or unknown) equal variances \( \sigma_k^2 = \sigma^2 \forall k \):

squared error model (constant offset \( \frac{1}{2} \log (2\pi\sigma^2) \) and factor \( \frac{1}{2\sigma^2} \) leave decisions unchanged)
general case:
we assume a functional dependence for each model of segment \( k \):

\[
\text{with a suitable parameter set } \lambda_k.
\]

The criterion is to find the segment boundaries \( n^K_1 \) such that the sum over all local squared errors is a minimum:

\[
\min_{n^K_1} \sum_{k=1}^{K} \min_{\lambda_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} [x_n - \hat{x}_n(k; \lambda_k)]^2 \right\}
\]

It is easy to see that we obtain the same type of dynamic programming recursion:

\[
G(k, n) = \min_m \left\{ G(k - 1, m) + \min_{\lambda_k} \sum_{i=m+1}^{n} [x_i - \hat{x}_i(k; \lambda_k)]^2 \right\}
\]
As before, we want to segment the sequence \( x_1^N \) into \( k = 1, \ldots, K \) segments. Each segment \( k \) is represented by a straight line with unknown parameters \( a_k \) and \( b_k \):

\[
\hat{x}_n(k; a_k, b_k) := a_k + b_k \cdot n
\]

The global criterion then is:

\[
\min_{n\frac{1}{K}} \sum_{k=1}^{K} \min_{a_k, b_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} \left[ x_n - (a_k + b_k \cdot n) \right]^2 \right\}
\]

implementation: see later (more general case: two–dim. signal with vertical least squares)
segmentation of one-dim. signals: straight line
SEGMENTATION OF IMAGE CONTOURS: TWO-DIM. SIGNAL
We are given the sequence of points \((x_1^N, y_1^N)\) in the two–dim. plane.

We want to segment this sequence into \(k = 1, \ldots, K\) segments. Each segment \(k\) is represented by a straight line with unknown parameters \(a_k\) and \(b_k\):

\[
y_k(x) := a_k + b_k \cdot x
\]

The global criterion then is:

\[
\min_{n_1^K} \sum_{k=1}^{K} \min_{a_k, b_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} \left[ y_n - y_k(x_n) \right]^2 \right\}
\]

[Note: This criterion does not take into account the difference at the segment boundaries \(y_{k+1}(x_{n_k}) - y_k(x_{n_k})\). However, incorporation of this difference into the criterion is possible at the expense of a slightly more complicated search, but this extension will not be dealt with here.]
segmentation of image contours (two–dim. signals)
We re-write the vertical least squares error:

\[ \sum_m [y_m - \hat{y}_m]^2 = \sum_m [y_m - (a + b \bar{x}_m)]^2 \]

For fixed parameter \( b \), minimizing over \( a \) results in:

\[ a = \bar{y} - b \bar{x} \]

Thus we obtain:

\[
\min_{a,b} \left\{ \sum_m [y_m - \hat{y}_m]^2 \right\} = \min_b \left\{ \sum_m [(y_m - \bar{y}) - b (x_m - \bar{x})]^2 \right\} \\
= \min_b \{ S_{yy} - 2 b S_{xy} + b^2 S_{xx} \}
\]

with the definitions of the elements of the scatter (empirical covariance) matrix:

\[
S_{xx} := \sum_m (x_m - \bar{x})^2 \quad S_{yy} := \sum_m (y_m - \bar{y})^2 \\
S_{xy} := \sum_m (x_m - \bar{x}) (y_m - \bar{y})
\]
vertical least squares: local optimization

We re–write the vertical least squares error:

\[
\begin{align*}
\min_b \{ S_{yy} - 2bS_{xy} + b^2S_{xx} \} &= \\
&= \min_b \left\{ S_{xx} \cdot \left[ \frac{S_{yy}}{S_{xx}} - 2b \frac{S_{xy}}{S_{xx}} + b^2 \right] \right\} \\
&= \min_b \left\{ S_{xx} \cdot \left[ \left( b - \frac{S_{xy}}{S_{xx}} \right)^2 + \frac{S_{yy}}{S_{xx}} - \left( \frac{S_{xy}}{S_{xx}} \right)^2 \right] \right\} \\
&= S_{xx} \cdot \left[ \frac{S_{yy}}{S_{xx}} - \left( \frac{S_{xy}}{S_{xx}} \right)^2 \right] \\
&= S_{yy} - \frac{S_{xy}^2}{S_{xx}} \\
&= \text{local error of segment}
\end{align*}
\]

implementation: running sums for $S_{xx}, S_{xy}, S_{yy}$
segmentation of image contours: orthogonal least squares
First, we define orthogonal least squares.

Each segment $k$ is represented by a straight line with unknown parameters $a_k$ and $b_k$:

$$y := a_k + b_k \cdot x$$

The global criterion then is:

$$
\min_{n} \sum_{k=1}^{K} \min_{a_k, b_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} (x_n - \hat{x}_n(k))^2 + (y_n - \hat{y}_n(k))^2 \right\}
$$

where for each observed point $(x_n, y_n)$, the point $(\hat{x}_n, \hat{y}_n)$ denotes the closest point on the line $y = a_k + b_k x$, i.e. the projection of each point $(x_n, y_n)$ onto the straight line.
We re–write the orthogonal least squares error:

\[
\sum_m \left( (x_m - \hat{x}_m)^2 + (y_m - \hat{y}_m)^2 \right) = \ldots
\]

\[
= \frac{1}{1 + b^2} \sum_m [y_m - (a + b x_m)]^2
\]

For fixed parameter \( b \), minimizing over \( a \) results in:

\[
a = \bar{y} - b \bar{x}
\]

Thus we obtain:

\[
\min_{a,b} \left\{ \sum_m \left( (x_m - \hat{x}_m)^2 + (y_m - \hat{y}_m)^2 \right) \right\} = \ldots
\]

\[
= \min_b \left\{ \frac{1}{1 + b^2} \sum_m [(y_m - \bar{y}) - b (x_m - \bar{x})]^2 \right\}
\]

\[
= \min_b \left\{ \frac{1}{1 + b^2} \left[ S_{yy} - 2 b S_{xy} + b^2 S_{xx} \right] \right\}
\]

with the same definitions of the elements of the scatter (empirical covariance) matrix as before
elements of the scatter (empirical covariance) matrix:

\[
S_{xx} := \sum_m (x_m - \bar{x})^2 \\
S_{yy} := \sum_m (y_m - \bar{y})^2 \\
S_{xy} := \sum_m (x_m - \bar{x}) (y_m - \bar{y})
\]

By taking the derivative with respect to \( b \), we obtain the quadratic equation:

\[
b^2 + b \frac{S_{xx} - S_{yy}}{S_{xy}} - 1 = 0
\]

There are two solutions:

\[
b = \frac{-(S_{xx} - S_{yy}) \pm \sqrt{(S_{xx} - S_{yy})^2 + 4 S_{xy}^2}}{2 S_{xy}}
\]

From the two solutions, we need the solution with the "+" sign for the minimum.
Alternative approach:
The problem we have formulated is equivalent to the representation error in PCA (= Principal Component Analysis = Karhunen–Loève transformation). In PCA, we have to find the smallest eigenvalue $\lambda > 0$ and the corresponding eigenvector $u \in \mathbb{R}^2$:

$$Su = \lambda u$$

with the scatter matrix $S = \begin{pmatrix} S_{xx} & S_{xy} \\ S_{xy} & S_{yy} \end{pmatrix} \in \mathbb{R}^{2 \times 2}$

The eigenvalues are obtained from the characteristic equation:

$$\det(S - \lambda I) = 0$$

$$(S_{xx} - \lambda) (S_{yy} - \lambda) - S_{xy}^2 = 0$$

$$\lambda^2 - \lambda (S_{xx} + S_{yy}) + S_{xx} S_{yy} - S_{xy}^2 = 0$$

We need the smaller of the two eigenvalues:

$$\lambda = \frac{1}{2} \left( S_{xx} + S_{yy} - \sqrt{(S_{xx} - S_{yy})^2 + 4S_{xy}^2} \right)$$

local error of segment: $= \lambda$

As before, we want to segment the sequence of points \((x_1^N, y_1^N)\) into \(k = 1, \ldots, K\) segments. Each segment \(k\) is represented by a circular arc with unknown center \((a_k, b_k)\) and radius \(r_k\):

\[
(x - a_k)^2 + (y - b_k)^2 = r_k^2
\]

The global criterion then is:

\[
\min_{n} \sum_{k=1}^{K} \min_{a_k, b_k, r_k} \left\{ \sum_{n=n_k-1+1}^{n_k} ([x_n - \hat{x}_n(k)]^2 + [y_n - \hat{y}_n(k)]^2) \right\}
\]

For each segment \(k\), the sum of squared errors can be re-written:

\[
\sum_n [x_n - \hat{x}_n(k)]^2 + [y_n - \hat{y}_n(k)]^2 = \sum_n \left[ r_k - \sqrt{(x_n - a_k)^2 + (y_n - b_k)^2} \right]^2
\]
segmentation of image contours: circular arcs
We consider a circular arc with unknown center \((a, b)\) and unknown radius \(r\):

\[
\begin{align*}
 r_n & := \sqrt{(x_n - a)^2 + (y_n - b)^2} \\
 r_n^2 & = (r + e_n)^2 = r^2 + 2r e_n + e_n^2
\end{align*}
\]

With the assumption \(|e_n| \ll r\), we obtain the approximation:

\[
 e_n \approx \frac{r_n^2 - r^2}{2r}
\]

For the total error of the circular arc, we obtain:

\[
\sum_n e_n^2 = \sum_n [r_n - r]^2 \\
\approx \sum_n \left( \frac{r_n^2 - r^2}{2r} \right)^2
\]
segmentation of image contours: circular arcs
Approximation:
to find the optimal parameters $a, b, r$, we neglect the denominator and consider the numerator only:

$$
\min_{a,b,r} \left\{ \sum_n [(x_n - a)^2 + (y_n - b)^2 - r^2]^2 \right\}
$$

The optimal value of the squared radius is given by the mean value of the $r_n^2$:

$$
\hat{r}^2 = \hat{r}^2(a, b) := \langle (x_n - a)^2 + (y_n - b)^2 \rangle
= \langle x_n^2 \rangle - 2a \langle x_n \rangle + a^2 + \langle y_n^2 \rangle - 2b \langle y_n \rangle + b^2
$$
Using this value, we obtain for the numerator:

\[
\min_{a, b, r} \left\{ \sum_n \left[ (x_n - a)^2 + (y_n - b)^2 - r^2 \right]^2 \right\} = \]

\[
= \min_{a, b} \left\{ \sum_n \left[ (x_n - a)^2 + (y_n - b)^2 - \hat{r}^2(a, b) \right]^2 \right\}
\]

\[
= \min_{a, b} \left\{ \sum_n \left[ x_n^2 - < x_n >^2 - 2a(x_n - < x_n >) + y_n^2 - < y_n >^2 - 2b(y_n - < y_n >) \right]^2 \right\}
\]

where the squares \(a^2\) and \(b^2\) have cancelled.

The resulting system of equations for \(a\) and \(b\) is LINEAR and thus can be easily solved.

note:

- use running sums (again) for efficiency
- quality of approximation ?? (better for larger \(r\))
segmentation of image contours: prior knowledge

global criterion for general case:

\[
\min_{K} \sum_{n_1}^{K} \min_{\lambda_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} \left( [x_n - \hat{x}_n(k; \lambda_k)]^2 + [y_n - \hat{y}_n(k; \lambda_k)]^2 \right) \right\}
\]

prior knowledge \( c(K) \) (= cost function) about number of segments \( K \):

\[
\min_{K} \left\{ c(K) + \min_{n_1}^{K} \sum_{k=1}^{K} \min_{\lambda_k} \left\{ \sum_{n=n_{k-1}+1}^{n_k} \left( [x_n - \hat{x}_n(k; \lambda_k)]^2 + [y_n - \hat{y}_n(k; \lambda_k)]^2 \right) \right\} \right\}
\]

prior knowledge about smooth (single !) parameters \( \lambda_k \) (for sets of parameters use \( ||\lambda_k - \lambda_{k-1}||^2 \)) using constants \( \gamma_k \):

\[
\min_{K} \sum_{n_1}^{K} \min_{\lambda_k} \left\{ \gamma_k \cdot (\lambda_k - \lambda_{k-1})^2 + \sum_{n=n_{k-1}+1}^{n_k} \left( [x_n - \hat{x}_n(k; \lambda_k)]^2 + [y_n - \hat{y}_n(k; \lambda_k)]^2 \right) \right\}
\]
prior knowledge:
put constraints on the sequence of segment types

solution:
use left–to–right graph of segment types (e.g. straight lines, arcs, ...)
represented by finite–state network:

\[ S \quad S \quad S \quad S \quad S \quad S \]

\[ S \quad S \quad A \quad S \]

\[ S \quad S \quad A \quad S \]

\[ S \quad S \quad \text{(circular) arc} \]

\[ S = \text{straight}, \ A = \text{(circular) arc} \]
segmentation of image contours: prior knowledge

example: technical line drawing
application of curve fitting to a mechanical construction drawing:
skeletized input image (left) and result of curve fitting (right)
application of curve fitting to a freehand drawing: drawing (left) and result of curve fitting (right)
IMAGE CONTOUR
image greylevel as a function of coordinates \((x, y)\):

\[(x, y) \rightarrow F(x, y)\]

notion of image contour:

- gradient \(f(x, y)\) of image \(F(x, y)\):

\[
f(x, y) := f_{\text{max}} - \sqrt{\left(\frac{\partial F(x, y)}{\partial x}\right)^2 + \left(\frac{\partial F(x, y)}{\partial y}\right)^2}
\]

or some other suitable type of gradient

note: suitable discretization of derivatives

- continuity constraint for the contour:

\[(x_n, y_n) \in R(x_{n-1}, y_{n-1})\]

where \(R(x, y)\) defines a suitable neighbourhood of \((x, y)\),
e.g. the 8–pixel neighbourhood

(in the following, let \(R^{-1}(x, y) := \{(x', y') : (x, y) \in R(x'y')\}\) denote the
set of possible predecessors for a point \((x, y)\);
usually the neighborhood is symetric, i.e. \(R = R^{-1}\)
optimization criterion:

$$\min_N \left\{ c(N) + \min_{(x_1^N, y_1^N)} \left\{ \sum_{n=1}^N f(x_n, y_n) \right\} \right\}$$

using some suitable cost function $c(N)$ for the length $N$ of the contour, e.g.

$$c(N) = \gamma \cdot (N - N_0)^2$$
To counteract the positivity of the cost and make the optimization problem well defined, we have to specify a region $R_B$ for the beginning point $(x_1, y_1)$ and a region $R_E$ for the end point $(x_N, y_N)$:

$$(x_1, y_1) \in R_B \quad (x_N, y_N) \in R_E$$

alternative cost function: use bonus $f_0$:

$$\min_N \left\{ \min_{(x_1^N, y_1^N)} \left\{ \sum_{n=1}^{N} [f(x_n, y_n) - f_0] \right\} \right\}$$

alternative cost function: normalize with respect to $N$:

$$\min_N \left\{ \min_{(x_1^N, y_1^N)} \left\{ \frac{1}{N} \sum_{n=1}^{N} f(x_n, y_n) \right\} \right\}$$
optimization criterion:

\[
\min_{N} \left\{ c(N) + \min_{(x_1^N, y_1^N)} \left\{ \sum_{n=1}^{N} f(x_n, y_n) \right\} \right\}
\]

DP recursion with backpointers:

\[
G_n(x, y) = \min_{(x', y') \in R^{-1}(x, y)} \left\{ G_{n-1}(x', y') + f(x, y) \right\}
\]

\[
B_n(x, y) = \arg \min_{(x', y') \in R^{-1}(x, y)} \left\{ G_{n-1}(x', y') + f(x, y) \right\}
\]

start traceback from optimal end hypothesis:

\[
\min_{n} \left\{ c(n) + \min_{(x, y) \in R_E} G_n(x, y) \right\}
\]
Image Contour: DP

\[ R^{-1}(x, y) \]

\[ n = 0 \quad n = 1 \quad n = 2 \quad n_{-1} \quad n \quad N \quad \text{max} \]
initialization: \[ G_0(x, y) := 0 \quad (x, y) \in R_B \]
\[ G_0(x, y) := \infty \quad (x, y) \notin R_B \]

for each length position \( n = 1, \ldots, N_{max} \) do

for each pixel \( (x, y) \) do

\[ G_n(x, y) := \min_{(x', y') \in R^{-1}(x,y)} \left\{ G_{n-1}(x', y') + f(x, y) \right\} \]
\[ B_n(x, y) := \arg \min_{(x', y') \in R^{-1}(x,y)} \left\{ G_{n-1}(x', y') + f(x, y) \right\} \]

start traceback from optimum end hypothesis:

\[ [N; x_N, y_N] := \arg \min_n \min_{(x, y) \in R_E} \{ c(n) + G_n(x, y) \} \]

for each length position \( n = N, \ldots, 1 \) do

\[ (x_{n-1}, y_{n-1}) := B_n(x_n, y_n) \]
computational complexity: $N_{max} \cdot X Y$

reduction of computational cost: DP beam search

compute score of best hypothesis of length $n$:

$$G_n^{min} = \min_{(x, y)} \{ G_n(x, y) \}$$

extend only hypotheses $(x, y)$ that are in an $\epsilon$ neighborhood:

$$\{(x, y) : G_n(x, y) \leq G_n^{min} + \epsilon \}$$
Results for contour finding: (a) gradient image; (b) minimum for each column; (c,d) contours found (algorithm I, $w = 20/w = 5$); (e,f) contours found (algorithm II, $B = 0/B = 140$)
Image Contour: Example

(e), (f)
model with prior knowledge:
reference contour with constraints on directions \((x_n - x_{n-1}, y_n - y_{n-1}), n = 1, \ldots, N\)

local cost function:

\[
c_n(x_n - x_{n-1}, y_n - y_{n-1}) := \gamma_n \cdot [(x_n - x_{n-1} - \delta x_n)^2 + (y_n - y_{n-1} - \delta y_n)^2]
\]

i.e. for each reference pixel \(n\), we assume directions \(\delta x_n\) and \(\delta y_n\) and a weight factor \(\gamma_n\)

optimization criterion using length model \(c(N)\):

\[
\min_N \left\{ c(N) + \min_{(x_1^N, y_1^N)} \sum_{n=1}^{N} \left\{ c_n(x_n - x_{n-1}, y_n - y_{n-1}) + f(x_n, y_n) \right\} \right\}
\]

DP recursion:

\[
G_n(x, y) = \min_{(x', y') \in R^{-1}(x, y)} \{ G_{n-1}(x', y') + c_n(x - x', y - y') + f(x, y) \}
\]
disadvantage of present model: length of contour must be specified beforehand.

improved model:
reference contour with forward, skip and loop transitions (like HMM), denoted by index
\( m = 1, \ldots, M \)

DP recursion with TWO indices \( n \) and \( m \):

\[
G_{nm}(x, y) := \min_{\delta=0,1,2} \left \{ \min_{(x', y') \in R^{-1}(x, y)} \left \{ G_{n-1,m-\delta}(x', y') + c_m(x - x', y - y') + f(x, y) \right \} \right \}
\]

\[
= f(x, y) + \min_{(x', y') \in R^{-1}(x, y)} \left \{ c_m(x - x', y - y') + \min_{\delta=0,1,2} \left \{ G_{n-1,m-\delta}(x', y') \right \} \right \}
\]

extension: penalties \( C(\delta) \)

\[
G_{nm}(x, y) := \min_{\delta=0,1,2} \left \{ C(\delta) + \min_{(x', y') \in R^{-1}(x, y)} \left \{ G_{n-1,m-\delta}(x', y') + c_m(x - x', y - y') + f(x, y) \right \} \right \}
\]
Image Registration and Matching

- one–dimensional registration and matching:
  = nonlinear time alignment (HMM = Hidden Markov model)

- two–dimensional registration and matching:
  - pseudo 2-D algorithm
  - Moore’s algorithm
  - Sakoe’s algorithm
Time Alignment Problem

Ney, SS 2003: *Segmentation in Images*  August 12, 2003  66
goal: comparing two time contours with NO fixed time axis

two time dependent signals:

- reference signal: $\mu_s \in \mathbb{R}, s = 1, \ldots, S$ (state = IDEAL time points)
- observed signal: $x_t \in \mathbb{R}, t = 1, \ldots, T$

task: find optimal time alignment

\[ t \rightarrow s = s_t \]

quantitative criterion:

\[
\min_{s_1}^{T} \left\{ \sum_{t=1}^{T} \left[ \mathcal{T}(s_t - s_{t-1}) + (\mu_{s_t} - x_t)^2 \right] \right\}
\]

with local distance:

\[
(\mu_{s_t} - x_t)^2
\]

and distortion penalty:

\[
\mathcal{T}(s_t - s_{t-1})
\]
auxiliary quantity:

\[ D(\tau, s) = \min_{s_1^{\tau}: s_{\tau} = s} \left\{ \sum_{t=1}^{\tau} \left[ \mathcal{T}(s_t - s_{t-1}) + (\mu_{s_t} - x_t)^2 \right] \right\} \]

DP recursion:

\[ D(t, s) = \min_{s'} \{ D(t - 1, s') + [\mathcal{T}(s - s') + (\mu_s - x_t)^2] \} \]

monotonicity of time scale:

do not allow backward transitions, i.e. \( \mathcal{T}(s - s') = \infty \) for \( s < s' \)

typical model with three types of transitions:

loop, forward, skip
For a reference signal $\mu^S_1$ and an observed signal $x^T_1$, the set of possible time alignment paths can be expressed by the so-called “trellis” or “lattice”:

The time alignment problem amounts to finding the optimal path through the trellis from the bottom left to the upper right corner.
This best state sequence associates a state with each observation sample. Some states may be skipped, some may have more than one acoustic vector associated with them. Such a mapping is called a “time-alignment”.

\[
\begin{align*}
x_1 & \rightarrow \mu_1 \\
x_2 & \rightarrow \mu_2 \\
x_3 & \rightarrow \mu_3 \\
x_4 & \rightarrow \mu_3 \\
x_5 & \rightarrow \mu_4 \\
x_6 & \rightarrow \mu_4 \\
x_7 & \rightarrow \mu_5 \\
\end{align*}
\]
Hidden Markov models

Idea: Represent each “part” of a signal by a state of a (stochastic) finite state machine.

At each time-frame $t$ the machine will “produce” an observation according to a distribution $p(x_t|s_t)$ (emission probability) which depends on its current state $s_t$.

Then the machine will go to the next state $s_{t+1}$ with probability $p(s_{t+1}|s_t)$ (transition probability).

The probability of the sequence pair $(x_T^1, s_T^1)$ is then

$$p(x_T^1, s_T^1) = \prod_{t=1}^{T} [p(s_t|s_{t-1}) \cdot p(x_t|s_t)]$$

Note: “stochastic finite state automaton”, “stochastic regular grammar”, and “Hidden Markov Model” are all equivalent formulations.
emission probability $p(x_t | s)$:

$$p(x_t | s) = \mathcal{N}(x_t | \mu_s, \sigma_s^2)$$

with a Gaussian distribution with state dependent mean $\mu_s$ and variance $\sigma_s^2$

transition probability $p(s | s')$: big table
Strictly speaking it is necessary to sum over all state sequences:

\[
p(x_T^1) = \sum_{\{s^T_1\}} \prod_{t=1}^{T} [p(s_t|s_{t-1}) \cdot p(x_t|s_t)]
\]

In most practical applications it is sufficient to consider only the most probable state sequence (Viterbi approximation):

\[
\text{argmax}_{\{s^T_1\}} \prod_{t=1}^{T} [p(s_t|s_{t-1}) \cdot p(x_t|s_t)] = \text{argmin}_{\{s^T_1\}} \left\{ - \log \prod_{t=1}^{T} [p(s_t|s_{t-1}) \cdot p(x_t|s_t)] \right\}
\]

\[
= \text{argmin}_{\{s^T_1\}} \sum_{t=1}^{T} \left[ - \log p(s_t|s_{t-1}) - \log p(x_t|s_t) \right]
\]
2-DIM. IMAGE MATCHING
Image matching: example
• map one image onto another one

• satisfy constraints (no ‘crossing’, no excessive stretching)

• we will formalize this concept in three steps and present DP algorithms for each resulting model:

  1. apply 1-D HMM to images:
     each column is regarded as one fixed vector and the columns are matched

  2. add flexibility in second axis (‘pseudo-2D’):
     use 1-D HMMs for each column separately (no dependency between columns)

  3. introduce dependency:
     use a real 2-D model (drawback: complexity)

Note: We do not restrict the mappings to affine or rigid transformations here. This other type of matching is usually performed by some global search over the transformation parameters with a suitable criterion (e.g. least squares or information theoretic measures).
From 1-D to 2-D

Now: comparing two images with image planes flexible, allow deformation

Two position dependent signals = images:

- reference image: \( \mu_{xy} \in \mathbb{R}, \ x = 1, \ldots, X, \ y = 1, \ldots, Y \)
- observed image: \( a_{ij} \in \mathbb{R}, \ i = 1, \ldots, I, \ j = 1, \ldots, J \)

Task: find optimal image alignment

\[
(i, j) \rightarrow (x, y) = (x_{ij}, y_{ij})
\]

1-D signal natural to regard as sequence \( t \mapsto t + 1 \) over \( t = 1, \ldots, T - 1 \)

This is not the case for 2-D signals.

Ney, SS 2003: *Segmentation in Images*  August 12, 2003
From 1-D to 2-D

First step: consider only ONE axis as flexible, second axis fixed
→ problem is the same as 1-D time alignment with vector-valued signals:

$$(i, j) \rightarrow (x, y) = (x_i, j)$$

Quantitative criterion:

$$\min_{x_1^I} \left\{ \sum_{i=1}^{I} \left[ T(x_i - x_{i-1}) + \sum_{j=1}^{J} (\mu_{x_i,j} - a_{i,j})^2 \right] \right\}$$

(assumption here: $Y = J$, i.e. images of same height)

compare HMM from before:

$$\min_{s_1^T} \left\{ \sum_{t=1}^{T} \left[ T(s_t - s_{t-1}) + (\mu_{s_t} - x_t)^2 \right] \right\}$$
Now introduce flexibility in second axis:

Consider each column vector of the image as 1-D signal and use best alignment.

\[(i, j) \rightarrow (x, y) = (x_i, y_{ij})\]

Quantitative criterion:

\[
\min_{x_i} \left\{ \sum_{i=1}^{I} \left[ T(x_i - x_{i-1}) + \min_{y_{ij}} \left\{ \sum_{j=1}^{J} [T(y_{ij} - y_{i,j-1}) + (\mu x_i y_{ij} - a_{ij})^2] \right\} \right] \right\}
\]

No interdependence between the HMMs for the columns is assumed, each image column is considered independently.

→ called pseudo-2-D HMM
Pseudo-2-D HMM

DP Recursion:

\[
D(i, x) = \min_{x'} \left\{ D(i - 1, x') + \left[ \mathcal{T}(x - x') + D(i, x)(J, Y) \right] \right\}
\]

\[
D(i, x)(j, y) = \min_{y'} \left\{ D(i, x)(j - 1, y') + \left[ \mathcal{T}(y - y') + (\mu_{x,y} - a_{ij})^2 \right] \right\}
\]
Pseudo-2-D HMM

Left-Right-Top-Bottom Model

Pseudo-2-D HMM for the word “hl”

“rotated” structures

→ independent DP for columns and rows
application: keyword spotting

Figure 7. In (a), the keyword “node” is correctly spotted on this document, which contained, in one test, 2,650 key words and 16,000 extraneous words. In (b), the keyword “node” also was successfully spotted in a document that included both size and slant transformations of the word.
Moore's algorithm

Pseudo-2-D maybe not suited, consider generalization of edit distance

1-D edit distance:
the minimum cost of changing one sequence into the other by the substitution, deletion, and
insertion of symbols in either sequence

recursive definition of $D(i, j)$ (cost of matching the sequences $a_1 a_2 \ldots a_i$ and $b_1 b_2 \ldots b_j$)

$$D(i, j) = \min\{D(i - 1, j) + d(a_i, \epsilon),$$
$$D(i, j - 1) + d(\epsilon, b_j),$$
$$D(i - 1, j - 1) + d(a_i, b_j)\}$$

for each matching step, there are 3 possibilities:

• skip the last symbol of $a$ or,

• skip the last symbol of $b$ or,

• match the last symbol of $a$ with the last symbol of $b$.

here: replace symbols by greyvalues $\rightarrow$ use $d(a, b) = (a - b)^2$
Moore's algorithm

Straightforward generalization is difficult, because skipping of an element from a 1-D signal leaves a 1-D signal in a canonical way, but skipping of a pixel from a 2-D images does not leave an image.

extension to 2-D: 15 possibilities (in general: \(2^D - 1\) – hypercube in 2D-dimensional space has 2\(^D\) vertices, one vertex can result from all others; in 1-D: square has 4 vertices)

→ means skipping of rows/columns

formula very complicated, informally: given two images \(A\) and \(B\) we have the possibilities to

1. skip the right column of \(A\)
2. skip the right column of \(B\)
3. skip the lower row of \(A\)
4. skip the lower row of \(B\)
5. skip the right column of \(A\) and the lower row of \(B\)
6. skip the lower row of \(A\) and the right column of \(B\)
7. match the right columns of \(A\) and \(B\)
8. match the lower rows of \(A\) and \(B\)
9. match the right columns of \(A\) and \(B\), skip the lower row of \(A\)
10. match the right columns of \(A\) and \(B\), skip the lower row of \(B\)
11. match the lower rows of \(A\) and \(B\), skip the right column of \(A\)
12. match the lower rows of \(A\) and \(B\), skip the right column of \(B\)
13. skip the lower row and the right column of \(A\)
14. skip the lower row and the right column of \(B\)
15. match the lower rows and the right columns of \(A\) and \(B\)

matching of 1-D sub-patterns with 1-D edit distance
Moore’s algorithm

Easy to implement

Difficult to interpret:

- which deformations are allowed at which cost?

No interdependence between matched or skipped columns / rows

Symmetric, allows skipping of pixels (and complete columns and rows) in both images
If pseudo-2-D not suited maybe “real” 2-D HMM (or planar HMM)

Interdependence between alignment in both directions

Task: find optimal image alignment

\[(i, j) \rightarrow (x, y) = (x_{ij}, y_{ij})\]

Quantitative criterion:

\[
\min_{x_{ij}^{I}, y_{ij}^{J}} \left\{ \sum_{i=1}^{I} \sum_{j=1}^{J} \left[ \mathcal{T}_{1}(x_{ij} - x_{i-1,j}) + \mathcal{T}_{2}(x_{ij} - x_{i,j-1}) + \right. \right.
\]
\[
\left. \left. \mathcal{T}_{2}(y_{ij} - y_{i-1,j}) + \mathcal{T}_{1}(y_{ij} - y_{i,j-1}) + (\mu x_{ij}, y_{ij} - \alpha_{ij})^{2} \right]\right\}
\]

DP algorithm is exponential in \(\min(I, J)\)

Can be shown to be NP-complete under some general assumptions
2-D Dependencies

\[ j \]
\[ \subseteq \]
\[ \subseteq \]
\[ i \]
\[ y_{ij} \]
\[ x_{ij} \]
Sakoe’s algorithm

\[
\mathcal{T}_1(\delta) = \begin{cases} 
|\delta - 1| & \text{for } \delta \in \{0, 1, 2\} \\
\infty & \text{otherwise}
\end{cases}
\]

\[
\mathcal{T}_2(\delta) = \begin{cases} 
|\delta| & \text{for } \delta \in \{-1, 0, 1\} \\
\infty & \text{otherwise}
\end{cases}
\]

constraints on displacements necessary for “monotonicity and continuity”

boundary conditions: \(x_{1j} = y_{i1} = 1\) \(x_{Ij} = X\) \(y_{iJ} = Y\)

2-D-interdependence \(\rightarrow\) exponential complexity even with DP
DP algorithm:

- \(xy_{ij}^J\) denotes last \(J\) pixel alignments at position \((i, j)\) (called “warped wake”), needed because of 2-D-interdependence:

\[
xy_{ij}^J : \quad (i - 1, j + 1) \mapsto (x_{i-1,j+1}, y_{i-1,j+1})
\]

\[
\vdots
\]

\[
(i - 1, J) \mapsto (x_{i-1,J}, y_{i-1,J})
\]

\[
(i, 1) \mapsto (x_{i,1}, y_{i,1})
\]

\[
\vdots
\]

\[
(i, j) \mapsto (x_{i,j}, y_{i,j})
\]

- \(WW(i, j)\) denotes set of all warped wakes \(xy_{ij}^J\) in position \((i, j)\):

\[
WW(i', j') = \{xy_{i'j'}^J\} = \left\{ \{x_{ij}, y_{ij}\} : (i = i' \quad \land \quad j \in \{1, \ldots, j'\}) \lor (i = i' - 1 \quad \land \quad j \in \{j' + 1, \ldots, J\}) \right\}
\]
Sakoe’s algorithm

DP algorithm (cont’d):

- $\text{Pred}(xy_{ij}^J)$ denotes set of possible predecessors of $xy_{ij}^J$
- auxiliary quantity $D(i, j, xy_{ij}^J)$ is minimal cost for alignment up to $(i, j)$ with the last $J$ pixels aligned according to $xy_{ij}^J$

$$D(i, j, xy_{ij}^J) = (\mu_{xy_{ij}^J(i,j)} - \alpha_{ij})^2 + \min_{xy \in \text{Pred}(xy_{ij}^J)} \left\{ \begin{array}{ll}
D(i - 1, J, xy) + T(\ldots) & \text{for } j = 1 \\
D(i, j - 1, xy) + T(\ldots) & \text{for } j > 1
\end{array} \right.$$
Examples: image $\alpha$, corresponding pixels of transformed image $\mu$, transformation grid, image $\mu$

- top: gray values, bottom: use of derivatives
Sakoe’s algorithm

\[ \text{cost: } (a(i,j) - \mu((x(i,j), y(i,j))))^2 \]

Ney, SS 2003: Segmentation in Images  August 12, 2003 92
